

Improving voluntary public good provision by a non-governmental, endogenous matching mechanism: experimental evidence

Christiane Reif^a, Dirk Rübbelke^b, Andreas Löschel^c

CAWM Discussion Paper No. 73

Abstract

Social norms can help to foster cooperation and to overcome the free-rider problem in private provision of public goods. This paper focuses on the enforcement of social norms by a self-introduced punishment and reward scheme. We analyse if subjects achieve to implement a norm-enforcement mechanism at their own expense by applying the theory of non-governmental norm-enforcement by Buchholz et al. (2014) in a laboratory experiment. Based on their theory without central authority and endogenously determined enforcement mechanism, we implement a two-stage public good game: At the first stage subjects determine the strength of penalty/reward on their own and in the second stage they decide on their contributions to the public good. We find that the mechanism by Buchholz et al. (2014) leads to a higher public good contribution than without the use of any mechanism. Only in a few cases groups end up with a zero enforcement mechanism. This result indicates that subjects are apparently willing to contribute funds for implementing an enforcement mechanism. Moreover, higher enforcement parameters lead to higher public good contributions in the second stage, although too high enforcement parameters lead to unreachable theoretical optima.

1. Introduction

Although cooperative behaviour in social dilemmas is observable (e.g. charitable giving, voting, recycling), the incentives for free-riding are still high for individuals. Therefore, the analyses of the private provision of public goods and its free-rider problem have a long theoretical and experimental tradition (e.g. Cornes and Sandler 1985, Bergstrom et al. 1986).¹ Despite research in sociology and psychology also in economic science attention has shifted to social norms. These norms can help to overcome the free-rider problem and are one of the key factors for cooperation (Voss 2001, p 110, Fehr and Fischbacher 2004a). Social norms are in general shared standards of how to behave appropriately in specific situations (see e.g. Horne 2001, Ellickson 2001, Voss 2001, Fehr and Fischbacher 2004a). This paper focuses on the enforcement of social norms by punishment and reward schemes and leaves aside the evolutionary dynamics of social norms discussed by other researchers (see e.g. Axelrod 1986, Sethi and Somanathan 1996, Ostrom 2000, Azar 2004).

The aim of this paper is to analyse whether subjects achieve to implement a norm-enforcement mechanism on their own costs to impose the provision of public goods. Therefore, we conduct a laboratory experiment based on the theory by Buchholz et al. (2014). In this theory the strength of a non-governmental enforcement mechanism is endogenously determined by the subjects themselves. At this model's first stage individuals decide on their contributions to finance an enforcement mechanism. At the second stage they decide on their contributions to the public good based on the established enforcement mechanism. The underlying social norm itself is taken as given and is determined by the average contribution to the public good. Deviations from this standard are punished or rewarded. Different to third party punishment approaches (e.g. Fehr and Gächter 2000, Fehr et al. 2002, Fehr and Fischbacher 2004a, 2004b), this sanctioning mechanism is endogenously implemented by the actors themselves and before the subjects decide on their public good contributions in the second stage.² So the subjects have to solve a two-fold public good problem: contributing to the enforcement mechanism and contributing to the public good.

Furthermore, the non-governmental norm enforcement mechanism by Buchholz et al. (2014) contributes also to the research on matching mechanisms, which are possible instruments to strengthen cooperation in social dilemmas. Matching mechanisms are strongly related to social norms because the individual provision depends on the others' provision of public goods, which shows conditional cooperation and adhering social norms in subjects' social environment (Guttman 2013). Theoretically, matching mechanisms 'manipulate' the effective price of a public good to incentivise the voluntary public good provision. Mechanisms with or without a central role of the government can be distinguished and there is a broad range of applications for matching schemes (Buchholz et al. 2011).

Among the related experimental literature on matching mechanisms without central authority is a laboratory experiment by Guttman (1986) based on the theory by Guttman (1978) in which the conditional cooperation increases the public good provision at lower costs. The results confirm that with the mechanism the contribution levels are higher than in the standard model of voluntary provision of public goods, i.e. in a setting where there is no such mechanism. Furthermore, Andreoni

¹ Also see Löschel and Rübbecke (2014) discussing voluntary provision and undersupply of public goods in an international context.

² For an approach with endogenously determined intensity of the social norm, see Lindbeck et al. (1999). Mengel (2008) provides another approach endogenizing the strength of the norm, defined as rising number of agents internalizing the social norm in a prisoners' dilemma interaction model.

and Varian (1999) implement the mechanism by Guttman (1978, 1987) as binding offers of side payments by one individual to another at the first stage and the decision on cooperation at the second stage in a prisoners' dilemma experiment. They find that the mechanism supports cooperation and the Pareto efficient outcome is achieved. However, decentralized mechanisms are limited when the group size is large because the personal interaction of agents as driving factor for cooperation is difficult in larger groups (e.g. Buchholz et al. 2014).

The theory by Falkinger et al. (1996) on a centralized matching mechanism is tested in an experiment by Falkinger et al. (2000) with a subsidy-tax scheme, in which the government rewards or penalises deviations from the average public good provision.³ Their results show that the mean contributions are higher in the mechanism treatment. Bracht et al. (2008) compare the two mechanisms in a laboratory experiment: compensation mechanism by Guttman (1978) with subsidizing contributions in a pre-stage and the Falkinger mechanism with centralized subsidy. The results show higher public good provision with both mechanisms compared to public good provision without any mechanisms. Concerning the predictions of the average level of contributions, the Falkinger mechanism performs better in their laboratory experiment. In contrast to the theory by Falkinger et al. (2000) which has an exogenous reward scheme, Buchholz et al. (2014) provide a theory without central authority and an endogenous norm-enforcement mechanism.

Schultz et al. (2007) and Alcott (2011) conduct field experiments closely related to the idea of social norms as non-governmental mechanism. In both field experiments the effect of descriptive and injunctive norms on subjects' energy conservation is analysed. In these non-price approaches Schultz et al. (2007) show that the initial levels of energy consumption have a crucial impact on the effect of descriptive norms leading to the so called boomerang effect,⁴ which can partly be absorbed by implementing an injunctive norm. Alcott (2011) finds that the effects of such norms conveyed via so-called 'home energy reports' are equivalent to an 11 to 20% short-run price increase.

In this paper we base our experiment on the theory by Buchholz et al. (2014) to evaluate the matching method and its suitability for coordinating the private provision of public goods. A two-stage design in a non-governmental mechanism environment is analysed. In particular the endogenous determination of an enforcement mechanism has not been experimentally tested in this context and we analyse whether subjects are willing to implement such a mechanism. We apply a non-linear payoff function to design the theory of Buchholz et al. (2014) in the same way as in Falkinger et al. (2000) or Bracht et al. (2008). In our setting without a central authority and an endogenously determined punishment/reward scheme, we find higher public good provision with the mechanism. Furthermore, subjects initially fund the enforcement parameter. In particular, only in a few cases groups ended with a zero enforcement mechanism, which shows that subjects are willing to contribute funds for implementing an enforcement mechanism. Moreover, higher enforcement parameters lead to higher public good contributions in the second stage. The results are in line with previous experiments with matching mechanism, but additionally provide information on the endogenous establishment of an enforcement mechanism.

³ Andreoni and Bergstrom (1996) also suggest an effective-price influencing mechanism involving a central authority. See Baker et al. (2009) who test different centralized matching mechanisms, either a lump-sum matching when reaching a threshold or one-to-one matching in a laboratory experiment.

⁴ Households initially consuming less than the average use the descriptive norm as justification to consume more.

2. Mechanism and Experimental Implementation

Mechanism

The theory is based on the paper by Buchholz et al. (2014) on voluntary public good provision influenced by social norms in a setting without governmental intervention. As the authors show, the considered mechanism establishing and enforcing norms may be effective in overcoming free-rider problems even when facing voluntary public good provision in large societies.

The model simultaneously handles two voluntary provision problems in a two-stage game: At the first stage, individuals voluntarily contribute to finance an agency establishing and enforcing a norm. At the second stage, individuals – influenced by the norm and its enforcement by the agency – decide on their voluntary provision to the public good. The specific norm applied is the average contribution of all the other individuals to the public good, so the budget for rewarding and punishing is balanced (see also Falkinger et al. 2000).

This non-governmental norm enforcement mechanism is to a certain extent related to previous mechanisms with or without a central role for the government. Among the decentral mechanisms is the matching approach first suggested by Guttman (1978), in which the free-rider problem in public good provision is addressed in a setting comprised of two stages. At the first stage, individual agents stipulate their matching rates, i.e. conditional contributions to the public good made per unit of the other agents' public good provision. At the second stage, agents provide their contribution to the public good, which is not made conditionally on other agents' provision.

The paper by Falkinger (1996) provides a mechanism with a central authority's intervention. Here, at the first stage, the government decides on rates rewarding individual agents' contribution deviating from the other agents' average contribution to the public good. At the second stage, individual agents set their voluntary contributions to the public good, taking into account the rewarding rates, which are exogenous for them.

In contrast, in Buchholz et al. (2014), the non-governmental norm-enforcement mechanism's reward rate is influenced by the agents through their voluntary contributions at stage one of the game, i.e. by the level of funds channelled towards the norm-enforcing agency. Thus, the reward rates are not exogenous anymore. Secondly, in the Falkinger (1996) scheme there is no transaction cost associated with the government's activity. The endogenously determined norm-enforcement causes costs, which are covered by the subjects' donations at stage one.⁵

The norm-enforcement model includes a scenario in which the group financing the enforcement mechanism (first stage) and the target group (second stage) differ as well as a scenario in which both may coincide. We focus on the latter, which is also in line with Coleman's (1990) classification of a conjoint norm targeting and benefiting the same individuals.

In the specification of the general setting in Buchholz et al. (2014), a Cobb-Douglas utility function of the form

$$U = c^\alpha G^{1-\alpha} \quad (1)$$

⁵ Please note that with altruistic punishment/reward (e.g. Fehr and Gächter 2002) or also endogenously determined punishment and reward schemes (see e.g. Ertan et al. 2009, Kosfeld et al. 2009) there is no decline of the effective price of the public good like in the matching approaches.

is employed where c is private consumption and G total public good supply. Private consumption c comprises the consumption of a private good y and ‘social esteem’ r generated through the norm-enforcement mechanism, i.e.

$$c = y + r \quad (2)$$

The public good G is defined as

$$G = \sum_{i=1}^n g_i \quad (3)$$

Prices of the individual goods are set equal to unity. Then, the monetary income I constraint reads as follows:

$$I = c_i + g_i + e_i \quad (4)$$

The reward r is positive for those contributing more and negative for those contributing less than the average of all other agents. The reward can be specified as:

$$r = \beta \left(g_i - \frac{G_{-i}}{n-1} \right) \quad (5)$$

The deviation from the average is weighted by parameter β , which represents the strength of the sanctioning mechanism. This strength – in turn – depends on the amount of donations $E = \sum_{i=1}^n e_i$ collected by the agency at stage one of the game, with $\beta = \beta(E)$, $\beta(0) = 0$, $\beta(E) < 1$, $\beta'(E) > 0$, and $\beta''(E) < 0$.

By maximizing (1) subject to (4), we obtain the following FOC:

$$MRS \equiv - \frac{\frac{du}{dc}}{\frac{du}{dG}} = 1 - \beta. \quad (6)$$

Equivalently to the exogenously fixed reward rate in Falkinger (1996), the effective price of public good provision is reduced by β (see right-hand side of (6)). To put it differently, the FOCs in the norm-enforcement model (Buchholz et al. 2014) and in the tax-subsidy model by Falkinger (1996) are formally equivalent. Yet, the driving forces for the decline in the effective price differ. In the norm-enforcement model, the decline takes place via an increase in an agent’s private consumption (augmentation of social esteem) by β per unit of his public good provision. In Falkinger’s tax-subsidy model, the respective agent receives a subsidy or conditional transfer of β monetary units per unit of his public good provision.

As the FOCs are decisive for an agent’s decision making and as these coincide in both models, we could consider either of both effective price reduction channels (monetary-subsidy payment or private-consumption ‘grant’) in our experimental analysis.⁶ It proved more feasible to employ the

⁶ Please take into account that the nominal unit prices of the private and public goods are assumed to be equal to unity.

‘subsidy interpretation’ in order to implement the norm-enforcement model by Buchholz et al. (2014) in an experimental setting. The specification of β in Buchholz et al. (2014) is:

$$\beta = 1 - \frac{1}{1 + En^{-\gamma}} \quad (7)$$

The parameter γ indicates the degree of rivalry in the use of funds available for the norm-enforcing agency. It is restricted to $\gamma \in [0,1]$, where zero stands for non-rivalry and one for full-rivalry. The degree of rivalry shows whether the norm could be enforced as a public good addressing all individuals equally or if the norm has to be enforced individually. We focus on non-rivalry in our experiment and therefore employ the following specification:

$$\beta = 1 - \frac{1}{1 + E} \quad (8)$$

Experimental Implementation

In the context of social norms, the social esteem parameter r can be interpreted as experience of guilt or shame related to so-called oughtness norms (Hechter and Opp 2001, p xiii).⁷ According to Hechter and Opp (2001), these types of norms are associated with moral obligations and subjects follow them no matter of the outcome. The theory by Buchholz et al. (2014) is specified for the experiment as ‘subsidy interpretation’ explained in the previous section. The social esteem parameter r is monetized like subsidies and taxes in the tax-subsidy model by Falkinger (1996). It can be negative or positive depending on the own contribution compared to the average contribution to the public good by the other players in the group. In monetizing the social esteem parameter r , we transform the underlying norm to a regulatory norm with social expectations (Hechter and Opp 2001). Subjects not complying with the norm, by deviating from the average in our case, are punished.

Deviating from the common linear payoff structure with boundary equilibria, the predictions of the theory are based on a Cobb-Douglas utility function with interior solutions.⁸ Fitting the experimental design to the based theory, the payoff function has to fulfil an underlying Cobb-Douglas utility function and the budget constraint described in (4). Therefore we implement the individual non-linear payoff function also used by Falkinger et al. (2000) and Bracht et al. (2008) based on Keser (1996):

$$\pi_i = 5 \cdot c_i - 0.05 \cdot c_i^2 + G \quad (9)$$

G is the sum of the group’s public good contributions (for a group of 3 subjects: $\sum_{i=1}^3 g_i$). This means that individuals get paid the group’s contributions from the public good. c_i is the remaining private

⁷ Please see Rege (2008) for a model in which the social status signals subjects’ non-observable abilities.

⁸ Here we use an approach with interior solutions due to three main reasons: Firstly, to set up a design close to the underlying theory with a Cobb-Douglas utility function. Secondly, to compare our results with those papers closely related to ours by Falkinger et al. (2000) and Bracht et al. (2008), who also use a non-linear payoff function. Thirdly, to overcome limits of boundary equilibria where decision errors can only lead to over-contribution, but not to under-contribution (see e.g. Andreoni 1993, Ledyard 1995, Keser 1996, Sefton and Steinberg 1996). Furthermore, zero contributions can be seen as socially unacceptable (see Keser 1996). For further discussion on voluntary public goods provision with interior solutions please see Laury and Holt (2008).

money for private consumption. In the *mechanism* treatment c_i depends on the decisions in the first and second stage.

$$c_i = I_i - e_i - g_i + \beta \cdot (g_i - \frac{G_{-i}}{2}) \quad (10)$$

The subjects get an endowment I_i with which they can decide on their contributions in the game. In the first stage they decide on the contribution to the enforcement mechanism e_i and in the second stage on the public good provision g_i . The enforcement parameter β results from summing up the group contributions ($E = \sum_{i=1}^3 e_i$) in the first stage and is calculated according to (8). The translation of the group investment E to the enforcement agency into the strength of sanctioning is provided in a table based on the equation (8) for the participating subjects.

In the baseline treatment, c_i reduces with only one stage and $\beta = 0$ to:

$$c_i = I_i - g_i \quad (11)$$

The equilibria predictions for the enforcement parameter β are based on the efficiency condition by Falkinger et al. (2000) with $\beta = 1 - (1/n)$, resulting for a group of 3 subjects in $\beta^* = 2/3$. Based on the payoff function (9) and (10), the equilibrium for the public good provision can be calculated with $g_i^* = -10/(\beta - 1)$. The following Table 1 provides the summary of our experimental design including the predicted interior equilibria.

Table 1: Summary of Experimental Design

Treatment	Group size	Endowment per period	MRS	E	β	Equilibria prediction
Baseline	3	50 LD	1	-	-	$g^B = 10$
Mechanism	3	50 LD	$1-\beta$	2	$2/3^*$	$g^M = 30^{**}$

Note: LD= laboratory dollar

*Based on the efficiency condition by Falkinger et al. (2000) $\beta=1-(1/n)$.

**Based on the payoff-function (8) and (9) the equilibrium can be calculated with $g_i = -10/(\beta-1)$.

3. Experimental Procedure

The subjects were randomly assigned to treatments and groups of three anonymous players. Subjects played either the *mechanism* or the *baseline* treatment.

The mechanism treatment is a two-stage public good game based on the theory by Buchholz et al. (2014). The subjects are endowed with €8 (50 LD) and decide at the first stage on their contribution to a norm-enforcement mechanism. By endogenously funding the mechanism on their own cost, they establish a norm defined as average contribution.

Before subjects decide on their contribution to the public good at the second stage, they experience the sum of all contributions in the group, the average contribution to the institution of the first stage, the resulting enforcement parameter β , and their remaining money on their private accounts (see z-tree screenshots in the appendix). At the second stage subjects contribute to the public good based on the resulting enforcement parameter β of the first stage. Beside the subjects' decisions on public good contributions, they additionally tell their expectations of the other group members' average contribution to the public good in the second stage. After their decision they learn about the sum of the group contributions to the public good, the average contributions, the income of the other group

members, and their own income distinguished by its origin (public good, private account, punishment/reward). All the information is anonymously provided and includes all previous periods (see z-tree screenshots in the appendix).

Our control treatment labelled as *baseline* is a simple public good game without mechanism, which reduces the *mechanisms* treatment to a one-stage game ($\beta = 0$). In both treatments the one shot games were repeated 10 times (plus two practice periods at the beginning) to allow for learning effects in both cases and to illustrate recurrent social interaction.

Experimental Protocol

The experiment was run in the laboratory mLab at the University of Mannheim, Germany. Students were recruited via the recruitment software Orsee (Greiner 2004). Overall, 108 subjects participated, with 51 subjects in *baseline* and 57 subjects in the *mechanism* treatment. They got a €4 show up fee and could additionally earn money from the game. The experiment was conducted with the software z-tree (Fischbacher 2007). The subjects were randomly assigned to the treatments and in each session randomly assigned to a group of three players. They were instructed about the rules of the game with the help of a manuscript including the payoff function with numerical examples, and control questions to check the understanding of these instructions (see appendix). We ensured that all subjects answered the entire control questions correctly before starting the experiment. The experiment included 2 practice and 10 payoff relevant periods. For both treatments they got an endowment of 50 laboratory dollar (LD) in each period. At the end of the experiment one round was randomly drawn for payment. The LDs were transferred in Euro with the rate 0.08. The average earnings (excluding the show-up-fee) were €12.24 in *baseline* and €12.36 in the *mechanism* treatment.⁹ After the game the subjects answered a questionnaire on risk, trust, rules and socio-demographic aspects.

4. Results

Contributions on the individual level to the public good (at the second stage) are on average 12.81 (standard deviation 4.52) for *baseline*, and 27.45 (standard deviation 10.85) for the *mechanism* treatment, which reveals higher contribution levels but also larger variation in the *mechanism* treatment (see Table 2 in the appendix). In the *baseline* treatment a fraction of 50.78% of individuals contribute close (0-10% deviation) to the equilibrium of $g^B = 10$ with 48.43% exactly contributing the equilibrium. On average, subjects in the baseline treatment spend 25.62% of their endowment to the public good. In the *mechanism* treatment this fraction ($27 \leq g_i^M \leq 33$) is only 13.15%, which we attribute to the complex design. The most frequent contribution was $g_i^M = 10$ with a fraction of 11.93% and $g_i^M = 20$ with a fraction of 10.53%. On average, subjects spend 54.94% of the initial endowment and 58.08% of the remaining endowment to the public good in the second stage. The following Table 2 provides the summary statistics.

⁹ Please note that the payout period was randomly drawn. Looking at the potential payoffs, the average earnings in baseline are €12.19 with a standard deviation of 0.59 and €12.46 in the mechanism treatment with a standard deviation of 1.23. The potential payoffs are significantly different ($p=0.0007$ Wilcoxon rank-sum test). The median of the potential earnings in baseline and mechanisms are significantly different from the earnings when reaching the equilibria (Wilcoxon signed rank test $p=0.0276$ for baseline and $p=0.0000$ for mechanism treatment).

Table 2: Summary statistics*

Treatment	1 st stage contribution to mechanism	min/max group contribution to mechanism in 1 st stage	Resulting β	Group contribution PG	min/max group contribution
Baseline	-	-	-	12.81	9.22/16.22
Mechanism	7.84	0/48	0.76	27.47	24.42/29.95

*Only payoff relevant periods are included, not the two training periods at the beginning.

The individual decisions over the ten periods are not independent. Therefore, we base further analyses on group average.¹⁰ We focus on the treatment level and additionally provide details on single groups.

The contributions of the two treatments are significantly different from each other based on a Kruskal-Wallis test ($p=0.0001$). Figure 1 shows the mean contributions of groups for the periods 1-10 by treatment and their confidence intervals. The graph for *baseline* shows declining contributions over time, as other experimental studies of private public good provision have shown before (see e.g. Ledyard 1995 or in non-linear settings Keser 1996, Sefton and Steinberg 1996, Falkinger et al. 2000, Bracht et al. 2008). The contributions in *baseline* are above the equilibrium of $g^B = 10$, except for the last period in which the group contributions fall below the theoretical equilibrium. Comparisons of the first and second half in the *baseline* treatment ($p=0.0000$ Wilcoxon signed rank test), as well as the first and the last period ($p=0.0000$ Wilcoxon signed rank test) show significant differences and provide evidence for an end round effect (e.g. Andreoni 1988, Laury and Holt 2008). The median of the group contributions differs significantly ($p=0.0000$ median test) from the theoretical equilibrium of $g^B = 10$. The average contribution over all periods in *baseline* is 12.81 with standard deviation of 2.13, revealing over-contribution. This result is in line with findings by Falkinger et al. (2000) and Bracht et al. (2008) with different group sizes (4 subjects and 2 subjects respectively).

In the *mechanism* treatment the contributions are higher than in *baseline* in all rounds. The difference is statistically significant ($p=0.0000$ Mann-Whitney U test). This is also true if we only compare the first half (period 1-5) or second half (period 6-10) of the treatments (both $p=0.0000$ Mann-Whitney U test). Figure 1 shows rather increasing contributions over time than declining contribution behaviour. Tests comparing the first and second half of the *mechanism* treatment ($p=0.0000$ Wilcoxon signed rank test) as well as a comparison of the first and the last round ($p=0.0000$ Wilcoxon signed rank test) in the *mechanism* treatment are significantly different. These results rather indicate a learning effect of the 10 payment relevant periods, which is in contrast to results by Falkinger et al. (2000) with exogenous parameter, where subjects played close to the equilibrium from the first periods onwards.

Although the second stage optimal contribution depends on the previously realized enforcement parameter ($g_i^* = -10/(\beta - 1)$), we first compare the public good contribution to the theoretical equilibrium of $g^M = 30$. This perspective enables us to relate our resulting provision levels with those of previous research with similar mechanisms, but exogenously given punishment parameters by Falkinger et al. (2000) and Bracht et al. (2008). Furthermore, from a theoretical perspective, the subgame-perfect equilibria are solved by backward induction in which the second stage equilibrium is solved first.

¹⁰ We base the tests on group average due to independency at this level (see Falkinger et al. 2000).

If we assume the optimal behaviour in stage one, resulting in a $\beta^* = 2/3$, the optimal contribution in equilibria would be $g^M = 30$. All the mean contributions in the *mechanism* treatment are below or at this equilibrium. There is a significant difference between the $g^M = 30$ equilibria and the actual median group contributions ($p= 0.0000$ median test). The average contribution over all periods is 27.45 with a standard deviation of 1.79, indicating under-contribution. Although the public good is underprovided, on average the contributions in *mechanism* are closer to the theoretical equilibrium than in *baseline*.

We calculate the confidence intervals (CI) for the two treatments in the manner of Falkinger et al. (2000) and Bracht et al. (2008) by bootstrapping to provide deeper insight than the previous reported standard deviations.¹¹ Figure 1 shows the resulting CIs for both treatments. The CIs of the treatments do not overlap in any round. The CI for the *mechanism* treatment is wider compared to *baseline*, which shows a larger variation of contributions in *mechanism*. The CI in *baseline* gets narrower in the end periods. In the *mechanism* treatment it is unchanged wide. The CI in *mechanism* includes the equilibrium in far more periods than in *baseline*. This indicates that playing the equilibrium in *mechanism* cannot be rejected.

Figure 1: Mean contributions periods 1-10 per treatment

The mean contributions of each group are provided in Table 4 for the baseline treatment and in Table 5 for the *mechanism* treatment in the appendix. The lowest (highest) mean group contribution over the ten rounds is 8.53 (18.20) in the *baseline* and 12.37 (44.35) in the *mechanism treatment*.

¹¹ As the basis for the calculation of the CIs we use individual contributions, but we accounted for learning effects by drawing period 1-10 from the same group. For the random draws with replacement we use 1,000 bootstrap samples and the 95% interval.

The range of contributions is not that wide in Falkinger et al. (2000) with an exogenously given parameter.

Looking at the group dynamics of individual's contribution over the ten periods (Figure 5 and Figure 6, appendix) in more detail, we see only in a few groups in the *baseline* treatment that the individual contributions vary, whereas most groups play the same strategy over the ten rounds with roughly equal contributions. In the *mechanism* treatment the individuals' contributions vary widely, but in more than half of the groups the individuals show stable behaviour in contributing roughly the same over the 10 periods. The individual level supports the previous results on group average: i) group contributions vary more widely in the *mechanism* treatment than in *baseline*, ii) first half contributions are higher and vary more widely than second half contributions in the *baseline* treatment whereas in *mechanism* the contrary is the case, iii) in *baseline* a tendency towards over-contribution and in *mechanism* towards under-contribution is observable like in Falkinger et al. (2000).

Result 1: The contributions in the mechanism treatment are significantly higher than in baseline. On average and on group level, under-contribution in the mechanism treatment is observable.

Nevertheless, the second stage equilibrium depends on the first stage's endogenously specified enforcement parameter. The mean group contribution to the enforcement mechanism is 7.84 (5.23% of the endowment) and the resulting β ranges from 0 to 0.98 (see Table 2).¹² However, the most individuals contribute between zero and five in the first stage and only 0.72% of the contribution decisions are higher than 25, which is the theoretical upper bound of first stage contribution (see

¹² The high values result from some very high contributions, which might indicate that subjects did not understand how the mechanism works.

Figure 2).¹³ The variation of the contribution to the enforcement mechanism in the last period only ranges from 0 to 7, which might be explained by learning effects. Almost 40% contributed nothing to the enforcement mechanism. This leads to the question how many groups result in a $\beta = 0$ and if their contributions in the second stage are then in line with the baseline equilibria. Overall eleven times $\beta = 0$ was realized by 5 different groups (with 4 group repeatedly realizing $\beta = 0$). The 42.42% of the individuals confronted with a $\beta = 0$ contributed 10 LD to the public good in the second stage, which is in line with the baseline equilibria. The theoretically optimal enforcement parameter with $\beta = 2/3$ was reached 19 times in 10 different groups. 10.53% of individuals played the equilibrium of 30 LD in the second stage when $\beta = 2/3$ was realized.

¹³ The upper bound of first stage contribution is based on the theoretical proposition that average contributions to the enforcement mechanism are never higher than half of the endowment by Buchholz et al. (2014), which is in our case 25.

Figure 2: Individuals' contribution to enforcement mechanism in stage 1 periods 1-10

Furthermore, an overview on the individuals' contributions to the enforcement mechanism (Figure 7, appendix) shows that in most groups low levels of first stage contributions are observable, which is in line with the theory. Nevertheless, in a small number of cases the group ends up with a zero enforcement mechanism. This is on the one hand due to the fact that for the implementation only one group member needs to contribute (Figure 3) and on the other hand that we ensured the understanding of the game by control questions.

Figure 3: Frequency of realized enforcement parameter periods 1-10

Result 2: Subjects are willing to establish norm-enforcement with their donations at the first stage.

The motivation for establishing the norm at the first stage could be strategical or intrinsic. A linear regression of the first stage contributions to the enforcement parameter shows neither significant effects of the socio-demographic nor of the behavioural variables (risk, trust, social-norm indicator)

of the post-questionnaire. We run regressions for each period. In period 1 none of the explanatory variables was significant, contrary to punishment settings in which trust increases punishment (e.g. Kocher et al. 2012).

In the second stage contributions to the public good theoretically depend on the realized enforcement parameter. A higher enforcement parameter should lead to higher contributions to the public good (see red line in Figure 4). However, as the subjects' budgets are restricted in the first place and they can only spend the remaining money after the first round, the theoretical optima are not reachable at levels of $\beta \geq 0.8$ (see shaded area in Figure 4). Figure 4 shows that the group contributions increase with higher enforcement parameter, but are in most cases below the theoretical optima. The increase of group contributions according to the higher enforcement parameter is in line with the theoretical predictions and with empirical findings by Bracht et al. (2008). They varied the exogenously given parameter and found higher contributions the higher the given parameter was.

Figure 4: Group contributions by realized enforcement parameter

Result 3: Mean group contributions tend to be higher the stronger the mechanism.

Result 4: Group contributions tend to be lower than the calculated optimum based on realized enforcement mechanism.

Furthermore, we analyse the contributions on the group level with a linear regression (Table 3). Supporting previous result 1, the contributions in *mechanism* treatment are higher than in *baseline*.

The influence of the enforcement parameter β on the contributions at the group level is significant and depends on the niveau, supporting the previous results 4 and 5.

In the second stage the effects of the expectations on public good contributions of the other group members and the realized enforcement parameter is not distinguishable. The expectations range from 0 to 50 with a mean of 23.8. It is not clear if the subjects base their decisions to contribute to the public good on their expectations or the realized enforcement parameter they are facing. Furthermore, individuals might base their expectations on the realized enforcement parameter (corr=0.3353). Nevertheless, a Pearson correlation of 0.6072 supports a positive relation of expectation and subject's own contribution. We can observe that 15.44% contributed the same amount as they expect as the other group members' average. 62.11% of the individuals (in the different rounds 1-10) contributed more than they expect as average contribution from the other two group members. Out of these individuals 42.97% (in the different rounds 1-10) invest in the enforcement mechanism in the first stage.

Result 5: Expectations on the contributions of the other group members and own contributions to the public good at the second stage are positively correlated.

5. Discussion and Conclusion

In this paper we focus on the enforcement of social norms induced by subjects who fund the enforcement mechanism themselves. We apply the theory by Buchholz et al. (2014) – an endogenous enforcement mechanism in a two-stage public good game – to a laboratory experiment. The design was also based on previous related laboratory experiments on different matching mechanisms by Falkinger et al. (2000) and Bracht et al. (2008). In our case, the individuals themselves introduced the enforcement mechanism by their own voluntary contributions, contrary to related experiments with an exogenously given parameter (see Falkinger et al. 2000, Bracht et al. 2008).

As in line with experimental results, the contribution in such games with a mechanism is higher than without. Even if Pareto efficient outcomes are not reached, the public good provision is higher in the mechanism case. In our sample only a few groups ended with a zero enforcement mechanism because only one contributing individual is needed to implement an enforcement mechanism. This result indicates that subjects are apparently willing to contribute funds for implementing an enforcement mechanism. This willingness to voluntarily contribute to the enforcement mechanism is

not necessarily due to altruistic motives, but might also be in line with pure self-interest. There is a strategic component involved: While direct voluntary contributions of one dollar to the intrinsic public good on stage two of the game brings about additional public good consumption only of a one-dollar worth, the same dollar spent on the first stage may induce a multiplier effect: the donated dollar might bring about a large number of individuals to contribute a value to the public good which is much higher than the initially spent dollar. And although the agent donating on the first stage also is induced to raise his contribution on the second stage, the multiplier effect may compensate for the higher burden this individual will face, i.e. he can gain from the rewarding scheme. The experiment also shows that the expected average contributions of the group members are correlated with the own public good provision. Further research would be needed to separate effects of expectations and the realized enforcement parameter on the public good provision. Moreover, further research would be needed to analyse the endogenous norm-enforcement mechanism in more detail in the laboratory as well as in the field, e.g. with different group sizes, heterogeneous players, distinction between finance and target groups, and alternative underlying social norms.

Nevertheless, our results might be instructive for non-governmental organizations which could exploit the norm-setting/enforcing mechanism in pursuing their objectives of private public good provision. Even though our reward scheme was monetized, the results indicate that people are willing to pay for such norm-enforcement. Furthermore, the orientation of the subjects towards the expected contributions of the other group members reveals that social norms strongly influence subjects in their decision making. Both the orientation on social norms and the willingness to contribute for the implementation of an enforcement mechanism for such norms can also provide implications for law makers, as legal enforcement is likewise based on social norms.

Welcome to our Experiment!

Thank you for participating. Please keep your mobile phones turned off during the whole experiment. Please do not talk to other participants. Now, please carefully read the following rules of the game.

If you have any questions, please raise your hand. A staff member will gladly answer your question.

Regardless of the course of the game you will receive 4 euros for your participation. During the experiment you can earn more money. Your additional earnings depend on the course of the game, i.e. on your own decisions and those of the other participants in the game. In the experiment, the only currency we calculate with is LaborDollars (LD). At the end of the experiment, the LD are converted into euro. The conversion rate is:

$$1 \text{ LD} = 0.08 \text{ EUR}$$

You make your decisions anonymously in the experiment. Only the staff will know your identity and your information will be kept confidential.

1. Rules

Three players take part in the game, i.e. apart from you, there are two other players. The composition of your group remains the same during the whole experiment. Each player has the same decision problem. You make your decisions anonymously. To ensure this, you will be given a player number for the duration of the game.

The three of you play **ten independent games in a row**. At the beginning of each game, you will receive an **initial endowment of 50 LD**. In each game, you make a decision for the use of your initial endowment. After the experiment, one of the ten games will be randomly selected for the payoff by the computer. Your income from the selected game will be converted from LD into euro. When you leave the lab, you will be paid this amount together with the lump sum of 4 euros. In the beginning, there will be **two trial games**, which are **not relevant for disbursement**.

One game consists of **two independent stages**, respectively. The overall result depends on your decisions and those of the other participants in your group. Your task in the game (just like that of the other players in your group) is to make decisions, in two stages, on contributions to an institution, a joint project, and a private account.

In the **first stage** you can invest in an institution. Through this institution, above-average contributions to a joint project will be rewarded and those below-average will be penalised.

In the **second stage**, you decide how many LD of the remaining amount from your initial endowment (**remaining endowment**) you want to contribute to a joint project and your private account.

2. Decision Situation

First stage

In the beginning of each game, every player receives 50 LD. In the **first stage**, you and the other players are asked to invest any amount in an institution. Depending on this investment, above-average contributions to a joint project will be rewarded and below-average contributions will be penalised in the second stage. Each LD that you do not invest in the first stage can be used as the remaining endowment for the second stage.

$$\text{Remaining endowment} = 50 - (\text{your investment in the institution})$$

The amount of investments of all group members determines the so called multiplication factor, according to **Table A**, which defines the intensity of the reward or the penalty. The first column in Table A indicates the sum of all investments in the institution. The second column indicates the corresponding multiplication factor. In the third column, the variation of the multiplication factor if one more unit is invested in the institution is listed. If, for example, 0 LD were invested, the multiplication factor in the second stage is 0. If, for example, a total of 3 LD were invested in the institution, the multiplication factor in the second stage is 0.75.

After entering your investment in the institution, you have to click on the "next" button. Afterwards, you cannot change your decision in the current game anymore. When all the group members made their investment decisions, the results of this stage will be displayed on the screen. In the upper half, you will find the results of all the previous games, and in the lower half, you will find the results of the current game.

Second stage

In the **second stage** of the game, you and the other players are asked to make a decision on the contribution to a joint project. For this purpose, you can use the remaining endowment from stage 1 and invest any amount in the joint project.

The remaining amount of LD for your private account depends on the investments of all group members in the institution in the first stage and their contributions to the joint project in the second stage. In the following, **direct and indirect contributions to the private account** will be distinguished. Thus, they present the total contribution to your private account.

Apart from entering your contribution to the joint project, you have to enter your expectation regarding the **average contribution of all group members to the joint project**. This expectation does not influence your payment and is not communicated to anyone. After entering your contribution to the joint project and the expected group average, you have to click the "Next" button. Afterwards, you cannot change your decision in the current game anymore

¹⁴ Note: In the baseline treatment there is no first stage.

After all the group members made their decisions for the contribution to the joint project and entered their expectations, the results of this game will be displayed on the screen. In the upper half you, will find the results of all the previous games, and in the lower half, you will find the results of the current game.

3. Calculation of Your Income

Income from the joint project

The income from the joint project is composed as follows for every member of the group:

$$\text{Income from the joint project} = \text{Sum of all contributions to the joint project}$$

Each group member receives the same income from the joint project. If, for example, the total sum of all contributions is 10 LD, each group member receives 10 LD as the income from the joint project.

For each LD that you contribute to the joint project, your income increases by one LD and so does the income of the other group members. Through your contribution to the joint project, the other group members also gain money, but you also gain through the contributions of the other group members to the joint project.

Income from your private account

a) Direct contribution to the private account

The part of the remaining endowment that you do not contribute to the joint project is the **direct contribution** to your private account.

$$\text{Direct contribution to your private account} = \text{Remaining endowment} - \text{your contribution to the joint project}$$

b) Indirect contribution to the private account

The indirect contribution to your private account depends on the investments of all group members in the institution in the first stage and their contributions to the joint project in the second stage. The **indirect contribution** is calculated as:

Indirect contribution to your private account

$$= (\text{Your contribution to the joint project} - \text{average contribution of the two other group members to the joint project}) \times (\text{multiplication factor according to Table A})$$

If, for example, 3 LD were invested in the institution in the first stage, this yields a multiplication factor of 0.75 according to Table A. If, for example, you contribute 10 LD to the joint project in the second stage and the other two group members have an average contribution of 20 LD, the indirect contribution to your private account is: $(10-20) \times$ (multiplication factor according to Table A). The indirect contribution is negative then (-7.5 LD). Conversely, if you contribute 20 LD to the joint project and the other two group members contribute 10 LD on average, the indirect contribution to your private account is positive. If the multiplication factor is the same (0.75), the indirect contribution is +7.5 LD.

In general, the indirect contribution to your private account is positive if your contribution to the joint project is **higher than the average contribution** of the other group members to the joint project. The indirect contribution to your private account is negative if your contribution to the joint project is **less than the average contribution** of the other group members to the joint project.

The multiplication factor determines how positive or negative the indirect contribution to the private account is. Consequently, the more was invested altogether in the institution by all group members in the first stage, the heavier a deviation from the average contribution of the other group members is rewarded or penalised. The lower the complete investment in the institution in the first stage, the more leniently a deviation from the average contribution in the joint project of the other group members is rewarded or penalised. Each LD of your contribution that exceeds the average contribution to the joint project of the other group members increases the indirect contribution to your private account by the multiplication factor determined in the first stage. In contrast, each LD of your contribution which is below the average contribution to the joint project of the other group members reduces the indirect contribution to your private account by the multiplication factor determined in the first stage.

Total contribution to the private account

The total contribution to the private account consists of the direct and the indirect contributions.

Total contribution to the private account

$$= \text{Direct contribution to the private account} + \text{indirect contribution to the private account}$$

The total contribution to the private account therefore depends on your contribution to the joint project, their relation to the contributions to the joint project of the other group members, as well as the investments in the first stage.

After the instructions you will find a schematic diagram of the correlations. In the upper half, you will find the diagram that shows the case in which you invest an additional LD in the joint project. In the lower half, you will find the diagram for the case in which an additional LD is invested in the joint project by the two other group members. Each LD that you contribute to the joint project, increases your income from the joint project by one unit and reduces the direct contribution to the private account by one unit. However, your contribution to the joint project increases in relation to that of the other group members, whereby the indirect contribution to your private account increases by the multiplication factor. **Each additional LD to the joint project does not reduce the total contribution to your private account by one unit, but by $(1 - \text{multiplication factor})$.**

If each of the two other group members increases his/her contribution to the joint project by one LD, your income from the joint project rises by 2 LD. In contrast, your indirect contribution to your private account by the multiplication factor since the average contribution to the joint project of the other group members increases by one unit compared to your contribution.

The income from your private account is calculated for all group members using the same formula:

$$\text{Income from private account} = 5 \times (\text{Contribution to own account}) - 0.05 \times (\text{contribution to own account})^2$$

The attached table B shows your income from the private account for every amount of your contribution to the private account. Unlike in the joint project, in which all group members profit from your contribution, only you can earn money from a contribution to your private account.

If you, for example, contribute 0 LD to your private account, your income from the private account is 0 LD. If you contribute 50 LD to your private account, your income from the private account is 125 LD (see table). The income from the private account solely depends on your contribution to your private account.

In the attached table B, you will find your potential total contributions to the private account in LD in the first column. In the second column, the respective income from the private account is listed in LD. The third column shows the change in income if the total contribution to your private account increases by one unit. The fourth column indicates the change in income if one more unit is invested in the joint project. You see that your income increases by **exactly one unit** if you or another group member **invests an additional LD in the joint project**. In contrast, the change in income from your contributions to your private account does not remain constant. The change in income is less the higher the total contribution to your private account already is. If your total contribution to the private account is already high, a further contribution to the private account generates a relatively low additional income from the private account. If, however, your total contribution to your private account is low, a further contribution to the private account generates a relatively high additional income.

Total income

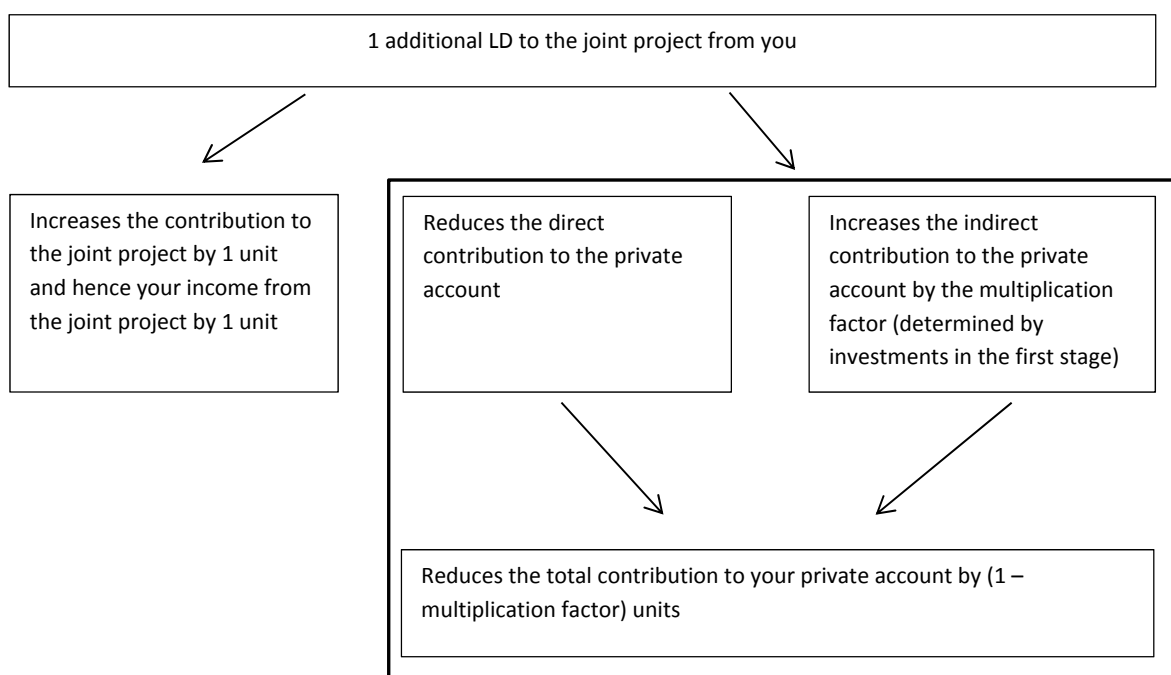

The total income is calculated from the income from the joint project and the income from the private account.

$$\text{Total income} = \text{Income from the joint project} + \text{income from the private account}$$

After the experiment, one of the ten games is selected randomly by the computer for payoff. Therefore, in **each** stage, you should act as if it was relevant to disbursement. Your income from the selected game will be converted from LD into euro. When you leave the lab, you will be paid this amount together with the lump sum of 4 euros.

In the beginning, there will be **two trial games**, which are **not relevant for disbursement**.
